## ESTIMATION OF STEM BORER DAMAGE IN RICE FIELDS*

BURTON T. ONATE**

Stem borer is considered as a major insect pest of rice. Considerable losses are incurred annually from the attack of this insect. However, precise methods of estimating the incidence of stem borer attack are not available. This paper will describe a simple but precise method of estimating the damage caused by this major insect pest of rice. These estimates with productivity data also can be used to explain the state and nature of yield loss.

Stem borer incidence in a rice field is usually measured as the number of dead hearts ( $X_{i}$ ) per hill at various stages of vegetative growth or the number of white heads ( $\mathrm{X}_{\mathrm{i}}{ }^{*}$ ) per hill at maturity. If we assume a finite universe of hills in a rice field, then the parameters may be designated as follows:

$$
\bar{x}=\sum_{i=1}^{N}\left(x_{1} / N\right)
$$

is the population mean of dead hearts per hill.

OT

$$
\bar{x}^{*}=\sum_{i=1}^{N}\left(X_{i}^{*} / N\right)
$$

is the population mean of nite heads der hill.

[^0]where
N is the size of the universe or the total number of hills.

The population variance is defined as

$$
s^{2}\left(x_{i}\right)=\sum_{i=1}^{N}\left(x_{i}-\bar{x}\right)^{2 /(N-1)}
$$

and

$$
\sigma^{2}\left(X_{1}\right)=[(N-1) / N] s^{2}
$$

for dead hearts. Similar equations are derived for $X_{i}^{*}$. In gentoo rad. $N$ is usually large so that numerically $/ S^{2}$ is equal to $\sigma^{2}$.

Incidence may also be expressed as the ratio of $X_{i}$ or $X_{i}^{*}$ to the number of tillers in a hill ( $Y$ ) or to the number of bearing panicles ( $\mathrm{Y}_{\mathrm{i}}^{*}$ ) at harvest time, respectively. These ratios are expressed as

$$
\begin{aligned}
& r_{i}=\left(X_{i} / Y_{i}\right) \text { for number of dead hearts to } \\
& \text { total number of tillers in a } \\
& \text { hill. }
\end{aligned}
$$

and

$$
\begin{array}{ll}
r_{i}^{*}=\left(X_{i}^{*} / Y_{i}^{*}\right) & \begin{array}{l}
\text { for number of white heads to } \\
\text { total number of bearing pani- } \\
\text { cles in a hill. }
\end{array}
\end{array}
$$

The parameter: in the population of dead hearts ( $X_{1}$ ) and total tillers $\left(Y_{1}\right)$ are

$$
\bar{A}=\sum_{i=1}^{N} r_{i} / N \quad \text { as the population mean of }
$$

and

$$
\begin{array}{ll}
\bar{Q}=(X . / Y .) & \text { as the ratio of population total } \\
& X . \text { and } Y . \text { (or ratio of population } \\
& \text { means } \bar{X} \text { and } \bar{Y}) .
\end{array}
$$

Similar formulas may bo given for the $X_{1}^{*} \cdot s$ and the $Y_{1}^{*} \cdot$. .

It is important to indicate which of the parameters $\bar{X}, \bar{R}$ or $\bar{Q}$ is being estimated. The variance of the estimator also can be derived.

## 1. Distribution of Incidence

The pattern of the distribution of dead hearts ( $\mathrm{X}_{\mathrm{i}}$ ), white head ( $X_{i}^{*}$ ) counts, $r_{i}$ or $r_{i}^{*}$ is shown in Figure 1 where a large proportion of the observations $X_{i}, X_{i}^{*} r_{i}$ or $r_{i}^{*}$ is zero.

## FIGURE I. PATTERN OF DISTRIBUTION OF INCIDENCE

This situation gives rise to large sampling variability of the original $X_{i}$ or $r_{i}$.

## 2. Pattern of Variability

As measured by the $\operatorname{cv}(\overline{\mathrm{x}})$ in percent, the variability of x is high. The variability is exhibited by the results given in Table 1, Figures 2 and 3 . Even with high mean incidence, the variability is still very high. Note the marked linear relationship between $S^{*}$ and $\mathrm{X}^{*}$ in Table 1 and Figure 1 and also thè relationship between $s$ and $\bar{x}$ in Figure 2. This was used by the author in devising a simple method of approximating the needed sample size for a given level of $\bar{x}$ (Oñate, 1964). ${ }^{\text {a }}$ Also, from Table 1, the size of sample needed to reduce the $\mathrm{cv}(\mathrm{x})$ to 10 percent will exceed 500 random hills. This situation calls for a simple but precise method of sampling for stem borer incidence.

## 3. Estimators

### 3.1 Random sampling

In dealing with incidence of stem borer attack, the parameters under study must be defined concisely, so that there will be no misunderstanding on what is being measured. These parameters where described earlier.

From the theory of a finite universe, our random sampling estimators of X and $\mathbf{S}^{\mathbf{2}}$ are

$$
\bar{x}=\sum_{i=1}^{n}\left(X_{i} / n\right)
$$

and

$$
e^{2}=\sum_{i=1}^{n}\left(X_{i}-\bar{x}\right)^{2} /(n-1)
$$

respectively, where
$\overline{\mathrm{x}} \quad$ la the sample mean.
$e^{2}$ is the sample variance.
and
n is the sample size.

The variance of $\bar{x}$ is

$$
\sigma^{2}(\bar{x})=[(N-n) / N] s^{2} / n
$$

Which simplifies into

$$
\sigma^{2}(\bar{x}) \doteq s^{2} / n
$$

If the finite population correction (fpc) is

$$
\{(N-n) / N\}: 1 .
$$

This variance $\sigma^{2}(\bar{x})$ is estimated by

$$
s^{2}(\bar{x})=[(N-n) / N] s^{2 / n}
$$

$$
s^{2}(\bar{x}) \geq s^{2 / n}
$$

## if [ $n / N]$ is very mall.

The results given in Table 1, Figure 2 and Figure 3 show that random sampling will result in estimators with very high sampling variability even for a large $n$.

### 3.2. Screening techniques

This technique was utilized by Oñate (Part III, 1964, pp. 94-95) in sampling for stem borer incidence. It is assumed in the application of this technique that the units, $\mathrm{U}_{\mathrm{i}}$ with $\mathrm{X}_{\mathrm{i}}=0$ can easily be distinguished in the field. If so, these units are screened and ignored in the samplnig procedure cedure (Cochran, 1953). The mean of the $\mathrm{Xi}=0$ is zero and the variance of the mean also is zero. By definition, variance for the whole population $\sigma^{2}$ is larger than $\sigma_{n z}^{2}$, the variance for the non-zero ( $n 2$ ) population. This relationshipis described below:

$$
\begin{aligned}
\sigma_{n z}^{2} & =\sum_{i=1}^{P N}\left(X_{i}=\bar{X}_{n z}\right)^{2} / P N \\
& =(V / P)\left[\dot{\sigma}^{2}-(Q / P) \bar{x}^{2}\right] \\
& =(V P)\left[. \dot{\sigma}^{2}-(P Q) \cdot \bar{X}_{n z}^{2}\right]
\end{aligned}
$$

$$
\bar{X}_{n z}=\sum_{i}^{P N} X_{i} / P N, \quad \begin{aligned}
& \text { is the population mean } \\
& \text { of the non-zeros. }
\end{aligned}
$$

$P$ is the proportion of $N$ that is non-zero."
$Q(1-P)$ is the proportion of $N$
that is zero.
and

$$
\overline{\mathrm{x}}=\mathrm{P} \overline{\mathrm{X}}_{\mathrm{nz}}
$$

Our estimator of $\bar{X}$. the population mean of hills attacked in the whole population is

$$
\overline{\bar{x}}=p \bar{x}_{n z}+Q \cdot 0
$$

where

$$
\bar{x}_{n z}=\left(\sum_{i=1}^{n^{*}} x_{i} / n^{*}\right)
$$

a* is the sample size in the non-zero population.
and
$P$ and $Q$ are as defined before.
The variance of $\overline{\bar{x}}$ is

$$
\begin{aligned}
\sigma^{2}\left(\overline{\bar{x}}=p \bar{x}_{n z}\right) & =P^{2} \sigma^{2}\left(\bar{x}_{n z}\right) \\
& =\left(P^{2} \sigma_{n z}^{2}\right) / n
\end{aligned}
$$

This form of $\sigma^{2}(\overline{\bar{x}})$ indicates that there are three sources which are responsible for the reduction of the variance of $\overline{\bar{x}}$ with the screening of $X_{1}=0$.

These sources are as follows:
a) $\sigma_{n z}^{2}$ will be smaller than $\sigma^{2}$ as indiesated by the conditions given above.
b) $p^{2}$ appears in the nuworater and $0<p<1$.
and
c) The finite population correction of $\sigma^{2}(\overline{\bar{x}})$ ill be smaller than in $\sigma^{2}(\bar{x})$. This relationship is given by

$$
\left[\left(N_{n z}-n *\right) / N_{n z}\right]<[(N-n *) / N]
$$

Note that the ordinary sample mean which is obtained without screening is $\bar{x}$ and $\sigma^{2}(\bar{x})=\sigma^{2} / n^{*}$ where we have ignored the fpc. In this formula. we can express the variance in corms of either $s^{2}$ or $\sigma^{2}$ from the relationship

$$
\begin{aligned}
\sigma^{2} & =[(N-i) / N] s^{2} \\
& =k s^{2} .
\end{aligned}
$$

The comparison will be in terms of $\sigma^{2}(\bar{x})$ and $\sigma^{2}(\overline{\bar{x}})$ Thus

$$
\left(\sigma^{2} / n^{*}\right)-\left(P^{2} \sigma_{n z}^{2} / \sigma^{*}\right) \geq 0
$$

Implies a gain in the screening method. From this rel'tionship. the relative efficiency can be expressed as

$$
\left[\sigma^{2} / P^{2} \sigma_{n 2}^{2}\right] 100 \%=(V / P)\left[1+Q / \operatorname{cv}\left(X_{i n_{2}}\right)^{2}\right] 100 \%
$$

which is a function of $P$ and $c u\left(X_{i n z}\right)$. The results are given in Table 2 for some values of $P$ and cu( $X_{i n z}$ ). Figure 4 illustrates the relationship. We can estimate $\sigma^{2}$ by $k s^{2}$ and $\sigma_{n 2}^{2}$ by $k^{\prime} s_{n 2}^{2}$. Our example estimate

Will be derived by the satio
$3 \quad\left(k s^{2} / k^{0} s_{n 2}^{2}\right) \geq P^{2}$
Which indicates the relationship necessary to attaln efficiency in the use of the screening method over the purely random case.

TABLE 2
RELATIVE EFFICIENCY IN PERCENT OF SCREENING TO NON-SCREENING OF ZEROS BY PROPORTION OF ATTACKED HILLS (P) AND COEFFICIENT OF VARIATION OF NON-ZEROS [CV ( $\mathrm{X}_{\mathrm{inz}}$ ) \%].

| Proportion ( P ) | Coefficient of variation [CV( $\left.\mathrm{X}_{\mathrm{in2}}\right) \%$ ] |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

| 1.00 | 100 | 100 | 100 | 100 | 100 | 100 | 100 |

Hith the data in Table 1, we can find out the reduction in the variance $\sigma^{2}(\overline{\bar{x}})$ as compared to $\sigma^{2}(\bar{x})$ The comparison between $\sigma^{2}(\overline{\bar{x}})$ and $\sigma^{2}(\bar{x})$ is given in Table 3 for 44 experiments. The gain in statistical preciaion ranges from 171 percent to 13.900 percent or on average of about 1250 percent .[. IRRI Annual Heport. 1964]. Lover $P$ values will result in higher relative officiencies.

[^2]3.3. Stratified sampling

A field may have sub-areas with different levels of incidence., Te can stratify the field in relation to $\bar{X}_{i}$ where $I=1.2 \ldots . . L$ refers to the number of strata or sub-fields. Thus, the overall mean 18

$$
\overline{\bar{x}}=\sum_{i}^{L} w_{i} \bar{x}_{i}
$$

where
$W_{i}=\left(N_{i} / N\right)$ is the weight of the $i^{t h}$ sub. area or may represent another weighing pattern which the entomologist may give himself.
and

$$
\mathbb{X}_{i}=\left(\sum_{j=1}^{N_{i}} X_{i j} / N_{i}\right) \quad \begin{aligned}
& \text { is the mean of the } i \text { th } \\
& \text { sub-area. }
\end{aligned}
$$

Within each $i^{\text {th }}$ subarea. we can screen out $X_{i j}=0$. Our estimator is

$$
\overline{\bar{x}}=\sum_{i=1}^{L} w_{i} x_{i}
$$

$$
\begin{aligned}
& =\sum_{i=1}^{L} W_{i}\left[P_{i} \bar{x}_{i}(n z)+Q_{i} \cdot 0\right] \\
& =\sum_{i=1}^{L} W_{i}\left[P_{i} x_{i}(n z)\right]
\end{aligned}
$$

and

$$
\sigma^{2}(\bar{x})=\sum_{i=1}^{L} w_{i}^{2} P_{i}^{2} \sigma^{2}\left[\dot{x}_{i}(n z)\right]
$$

$$
\begin{aligned}
& =\sum_{i=1}^{L} w_{1}^{2}\left(p_{1}^{2} / p_{1}^{*}\right)\left\{\left(q_{1}^{2} / p_{1}\right)-\left(\bar{x}_{1}^{2} q_{1} / p_{1}^{2}\right)\right\} \\
& =\sum_{1=1}^{L} m_{1}^{p}\left(p_{1} \sigma_{1}^{2}-q_{1} p_{2}^{2} \bar{x}_{1}^{2}(n z)\right] / n_{1}^{*}
\end{aligned}
$$

The finite population correction may be inserted into this variance formula.

In actual sampling work, precise estimate of $P_{i}$ and $Q_{i}$ can be obtained from a relatively larger sample ( $n^{* *} \gg n^{*}$ ) while an estimate of $\bar{X}_{i}(n z)$ Le given by $X_{i(n z)}$ from the smaller sample $n_{i}^{*}$. In fact, the estimate of $\sigma_{i(n z)}^{2}$ can be obtained from the sample variance formula.

$$
s_{i(n z)}^{2}=k \sum_{j}^{n_{1}^{*}}\left[x_{1 j(n z)}-\bar{x}_{i(n z)}-\right]^{2} /\left(n_{1}^{*}-1\right)
$$

and the estimate of $\left[P_{1}^{2} \sigma_{1(n z)}^{2}\right] / a_{1}^{*}$ is obtained from

$$
\left.\hat{l}_{k} \hat{P}_{1}^{2} s_{1(n z)}^{2}\right]_{1}^{1 / n}
$$

where
$\hat{P}_{i}$ is derived from a larger sample $n_{1}^{* *} \gg^{\circ} n_{\|}$. The size of sample for each stratum may be given as

$$
n_{1}^{*}=n\left(N_{1} s_{1} / \sum N_{1} s_{1}\right)
$$

where

$$
S_{1} \text { ar be expressed } \ln \text { terms of } \bar{X}_{1} \text {. }
$$

### 3.4. Measurement of ratios

Another type of measurement usually employed in stem borer experiments is the ratio

$$
r_{i}=\left(X_{i} / Y_{i}\right)
$$

where
$X_{i}$ is the count of dead hearts in the $\mathrm{i}^{\text {th }}$ hill,
and $\quad Y_{i}$ is the count of tillers in the $i^{\text {th }}$ hill.
It is important to note that our $U_{i} \cdot s$ are the hills. If a random aqmple of size, $n$ hills is obeainedthen we have the mean of ratios,

$$
i=\left(\sum_{i=1}^{n} r_{i} / n\right)
$$

as an unbiased estimate of

$$
\bar{B}=\sum_{i=1}^{N}\left(r_{i} / N\right)
$$

which is the population mean of ratios $\left(r_{i}{ }^{\prime s}\right)$ on a hill basis.

There is another ratio which is termed as the populaton ratio of means or totals and this is defined as

$$
\begin{aligned}
\mathbf{Q} & =(\mathbf{X} / \mathbf{Y}) \\
& =(\mathbf{X} . / \mathbf{Y} .)
\end{aligned}
$$

where
$X$ and $Y$ are population means per hill
and
$X$. and $Y$. are population totals of hills respectively.
In the literature, it is not very clear which of $\mathbf{R}$ or $\mathbf{Q}$ is the parameter which is estimated although in most cases the estimator used is termed the sample ratio of means or totals and this estimator is defined as

$$
\begin{aligned}
q & =(x / y) \\
& =x^{\prime} / y^{\prime}
\end{aligned}
$$

where $\vec{x}$ and $\bar{y}$ are sample means,
and

$$
x^{\prime} \text { and } y^{\prime} \text { are sample totals. }
$$

Both $\bar{r}$ and $\bar{q}$ are biased estimates of $\bar{Q}$ but $\bar{q}$ is easier to compute and has a lower upper bound in the relative bias as compared to $\bar{r}$. Note that in this form $\bar{q}$ is identical to the binominal estmiator $\overline{\mathrm{p}}$ of $\overline{\mathbf{P}}=\mathrm{X} . / \mathrm{Y}$. since each tiller is observed as either attacked and that

$$
\tilde{p}=\sum_{i j}^{N}, M_{i} x_{i j} / \sum_{i}^{N} M_{i} .
$$

is estimated by

$$
\bar{p}=\sum_{i j}^{n_{j} \mathbb{w}_{i}} x_{i j} / \sum_{i=1}^{n} m_{i}
$$

Where $N$
N
M is the total number of tillers in 1 the universe.
and

Note that in the binomial, each tiller is assumed to be independent of getting attacked or not. However, we notice that there is a clustering of tillers in a hill. As such there is a tendency for tillers within a given hill to be alike. Also in $\bar{q}$ and $\overline{\mathbf{Q}}$, our units, $\mathrm{U}_{\mathrm{i}}$, are the hills or clusters of tillers while in $\overline{\mathrm{p}}$ and $\overline{\mathrm{P}}$, our units are the tillers. Thus, the universe
in $\overline{\mathrm{Q}}$ is smaller than the universe in $\overline{\mathrm{P}}$. Generally, and in actual sampling work, the hill or some larger unit is the sampling unit and not the tiller within the hill. Thus, the variance
tiller within the h..... Thus, the variance of 4 . $\sigma^{2}(\bar{q})$ is the more appropriate variance than $\sigma^{2}(\bar{p})$. Note that $\overline{\mathrm{p}}$ estimates $P$ (population proportion) whir. is identical to $\bar{Q}$.

The ratio estimator, $\bar{q}$. has a varianen

$$
\sigma^{2}(\bar{q})=[(N-n) / N n] \bar{q}^{2}\left[c_{x x}+c_{y y}-2 c_{x y}\right]
$$

where

$$
\begin{aligned}
& C_{x x}, C_{y y} \text { are the square of the coefficient of } \\
& \text { variation }(C V) \text { of } X_{i} \text { and } Y_{i} \text {, re- } \\
& \text { spectively, }
\end{aligned}
$$

and

$$
\begin{aligned}
& C_{x y} \text { is the similar CV definition for the } \\
& \text { covariance. }
\end{aligned}
$$

This variance of $q$ is estimated from sample ( $\Sigma^{\prime}$ ) by

$$
s^{2}(q)=\left[(N-n) / N n(n-1) \dot{y}^{2}\right]\left[\Sigma^{\prime} x_{i}^{2}+\bar{q}^{2} \Sigma^{\prime} y_{i}^{2}-2 \bar{q} \Sigma^{\prime} x_{i} y_{i}\right] \cdot
$$

Note that numerically $\bar{p}=$ q. but the variances will differ as shown above. It is important to remember that the units are the hills and not the tillers. Thus. the binomial variance, $\sigma^{2}(\tilde{p})$ is not the appropriate measure.

The relative efficiencies of the screening method for $\bar{x}$ and $\bar{r}$ as the estimators are shown in Tables ja and 36 , respectively for experiments conducted during the years 1962 to 1964.

## 4. Summary and Conclusions

Data from experiments on stem borer incidence from the International Rice Research Institute (IRRI) fields for the years 1962 to 1964 were used to study the problems of estimation of parameters on stem borer incidence.

Results of these analyses and those from the available literature indicate that the assumption of a finite universe $\left(\mathrm{U}_{\mathrm{i}}\right)$ and finite population ( $\mathrm{X}_{\mathrm{i}}, \mathrm{X}_{\mathrm{i}}^{*}, \mathrm{X}^{* *}$ ) is sound for studies rf stem borer incidence. This paper has classified the parameters used in the stem borer incidence and the estimators relevant to each parameter.

The concept of the tiller in the hill as the observational unit (ou) was distinguished from the concept of the hill as the sampling unit (su). Thus, the ratio estimator with the hill as the ( su ) is the more appropriate than the binomial estimator which uses the tiller or (ou) as the unit.

For counts, the technique of screening out the zeros will result in large relative statistical efficiency averaging about 1300 per cent. The coefficient of variability (cv) of the estimator with screening will be reduced by $(1 / \sqrt{ } 13)$. If the cv of the estimator for random sampling is 20 per cent, then the cv of the estimator using screening will be on the average about 6 per cent only. For ratios, the relative efficiency is about 650 per cent. From these results, it is concluded that screening can be used as a precise technique for the estimation of stem borer incidence in experimental fields. This technique was utilized in applied research plots in farmer's paddy fields.

The concepts in the method of sampling with the screening out of zeros were extended to stratified sampling. In conjunction with crop cutting and/or interview survey, the relationship between stem borer incidence and yield may be obtained and yield loss curve can be derived.
